INTRODUCTION

SITE LOCATION

The site of the West Lake Landfill is located at 13500 St. Charles Rock Road in Bridgeton, Missouri (see Figure IN-1). The site of the old landfill in approximately acres, was placed on the alluvium of the Missouri River, and part was placed in previously existing rock quarry pits at the edge of the Missouri River Valley. Current landfilling is being carried out in a deep quarry placed in bedrock formations which are hydrologically isolated from the old landfill, and is therefore not part of this study.

PURPOSE

The hydrogeologic investigation was intended to obtain the data necessary to define the groundwater flow patterns and flow rates in the vicinity of the site, and determine the nature and distribution of any contaminants which may occur in the groundwater. It was also intended to provide a basis for planning a program of long-term groundwater quality monitoring at the site and background data for development of a remedial action program if conditions warrant.

Because the geologic setting and stratification of the subsurface materials beneath the site influence the groundwater occurrence and flow pattern, a major part of the investigation was directed towards defining the site geology and engineering properties of the subsurface materials. In addition, a certain amount of data was available from previous investigations, and an analysis was made of the usefulness of that information.

WSTINT.HYI

SCOPE

To analyze the hydrogeologic conditions at the site, field work was performed in two phases, after evaluating existing subsurface information, as well as available geological publications. Soil samples were obtained from 15 borings drilled for this investigation. Selected samples were tested for soil engineering properties, including moisture content, density, grain size, and for fine grained soils, Atterberg limits. Piezometer standpipes were installed in the borings, both to future water level measurements and in some cases to obtain groundwater samples for chemical analysis. Twenty of the previously existing piezometers on the site were found to be usable for water level determinations. Therefore, water levels were measured periodically in a total of 35 piezometers. The piezometer tubes are screened at various depths in the alluvial aquifer, to determine the hydraulic head and groundwater flow direction at different levels in different and areas of the site.

Groundwater samples were collected from 18 selected monitoring wells. The wells were selected to provide data at widespread locations on the site and at different depths within the alluvium. Two rounds of sampling were performed, one in winter and one in summer. The water samples were chemically analyzed in the laboratory for full priority pollutants.

To assist in interpretation of the data from this investigation, maps and subsurface profiles have been prepared showing the hydraulic head in the aquifer, and the distribution of chemical constituents in the groundwater. The maps and profiles are included in this report.

The analysis of the data includes an assessment of the impacts of the landfill on the groundwater of the area. The analysis was applied towards recommending a plan for future, long-term groundwater monitoring.

* * * * *

PART I

GEOLOGICAL SETTING

In the St. Louis vicinity, the bedrock stratigraphic sequence consists primarily of limestone and dolomite which were deposited, for the most part, in shallow epicontinental seas. Geologic deposits range in age from Precambrian to Holocene. The Precambrian rocks are the only units that do not crop out in the St. Louis area; they are, however, present in the subsurface. Many periods of emergence, nondeposition or erosion are implied by the disconformities and local unconformities observed in surface exposures and well data.

Bedrock in the West Lake area consists of limestones of the Pennsylvanian and Mississippian (Ref. 1). A thin deposit of the Cherokee Group systems (Pennsylvanian) occurs nearest the surface at the site. The Cherokee consists primarily of limestone in this area, but may also contain interbeds of other clastic sedimentary rocks, primarily shales (Ref. 2). Below the Cherokee are Mississippian limestones of the Meramecian series. The Ste. Genevieve limestone (approximately 30 feet thick), if present here, is apparently quite thin. Occurring stratigraphically below the Ste. Genevieve is the St. Louis Formation (approximately 100 feet thick). The Saint Louis is the primary limestone which is presently mined at the West Lake Quarry. Below the St. Louis Formation is the Salem Formation (approximately 100 to 160 feet thick), a limestone which is also being quarried at West Lake. The Warsaw Formation occurs below the Salem. The Warsaw is a shaley limestone with some shale interbeds (approximately 80 feet thick) and quarrying probably terminates near the top of this stratum.

WST1.HYI I-1

The present structural attitude of the rock units is the result of compressional, tensional and uplifting forces which moved and altered the units from their original depositional positions. These forces have folded, fractured, faulted and tilted the rocks in the St. Louis area to a moderate degree, and the resulting structures are superimposed on a regional dip or large-scale tilting of the rock units of from 60 to 80 feet per mile to the northeast. Locally, in the West Lake area, the bedrock strata are nearly horizontal with minimal fractures.

Alluvium, including thick deposits of glacial outwash and some river terrace deposits fills the deeply eroded bedrock channel formed by the Missouri River during the Pleistocene Epoch. The thickness of the alluvium is variable because of irregularities in the bedrock surface upon which it was deposited, but the maximum known thickness is approximately 150 feet. The alluvium is composed of clay, silt, sand and gravel. In general, the alluvium becomes coarser-grained with depth. Occuring on the Missouri River valley bluffs above the river valley are thick loess deposits. These loess deposits directly overlie the bedrock of the uplands.

The West Lake Landfill site is located on the Missouri River valley's east wall (Figure I-1). Bedrock in the landfill vicinity occurs near the surface at the point of transition between the loessial bluffs to the east and the alluvial valley to the west. The generalized line of transition is shown on Figure I-2. The bedrock surface drops off sharply below the valley to the west and the loess bluffs rise abruptly above the bedrock to the east. The quarry operations occur generally where the bedrock is nearest the surface at the edge of the valley

WST1.HYI I-2

wall, and past landfill operations have generally extended from the quarry area westward on the alluvium. The surface of the alluvial deposits is quite level, although small drainageways and channels create slight depressions and terraces.

Figure I-1 is a generalized, vertically exaggerated geologic profile across the Missouri River valley in the vicinity of the site. This profile illustrates the relationships between the impervious bedrock, the alluvial aquifer, and the general range of water table elevations in the aquifer.

Figure I-2 is a site plan showing the topography of the site and the locations of the borings drilled and/or used in this investigation. Also shown on Figure I-2 are the approximate boundaries of the landfilled area.

Figure I-3 is a detailed geologic profile along the southwest perimeter of the existing landfill. The location of the line of the detailed geologic profile is shown on Figure I-2. Figure I-3 shows the relationships between the bedrock and the overlying alluvium, comprised of the coarse-grained aquifer and the uppermost, generally fine-grained aquitard. Also shown are water levels in piezometers at times of relatively high river stage (and consequent high water table in May 1984) and relatively low river stage (and consequent low water table in February 1984). Also, note that the water table intersects the ground surface in the drainage ditch adjacent to the road at the northern end of the profile line.

* * * * *

PART II

SUBSURFACE INVESTIGATION

A. PRELIMINARY AND PRIMARY INVESTIGATIONS AND PREVIOUS STUDIES

A preliminary subsurface field investigation of the site was conducted in August, 1984. The field and laboratory work performed for this investigation were intended to supplement information investigations of this site, and to obtain additional information on groundwater conditions. The preliminary investigation included drilling and sampling nine borings, four of which extended to bedrock. The locations of the borings (which are numbered in the 80's) are shown on Figure I-2. information presented in the report entitled "Hydrogeologic was Investigation - West Lake Landfill - Preliminary Phase Report", January, 1985 by Burns & McDonnell. After the preliminary phase of the project was completed and the data evaluated the primary phase was begun. Six test borings were drilled and piezometers installed in April and August, 1985. All six test borings were drilled to bedrock. The locations of these borings (numbered in the 90's) are shown on Figure I-2.

Existing piezometeres (numbered in the 50's, 60's, and 70's) were evaluated for soundness of construction by field inspection and response to water level changes and found to be acceptable for indication of water levels (hydraulic head). Therefore, data collected from these piezometers was utilized to evaluate groundwater gradients and flow directions.

WST2.HYI II-1

Piezometers were installed in all borings for both phases for purposes of water level determination were used for obtaining water samples for chemical analysis. Some of the piezometers were clustered with existing monitoring wells or with each other resulting in eight clusters of water level monitoring points that can be used to detect possible differences in water pressure (hydraulic head) with depth. Boring depths ranged from 22.0 feet to 143.3 feet. Soil samples were obtained on 5- or 10-foot centers in all borings according to ASTM standards. Using thin-walled Shelby tubes, 12 undisturbed soil samples were obtained at various depths in the borings. Using standard penetration test procedure, 156 split-spoon samples were also obtained.

The geologic logs of all of the borings drilled for this investigation are included in Appendix A.

B. MONITORING WELL PROGRAM

Piezometers were installed in each boring according to the typical construction diagram in Appendix B. Specific construction details for piezometers are noted on the respective boring logs. When piezometers were not responding to changing water levels in the aquifer they were developed by evacuating with compressed air until clear water flowed freely into the piezometer. Piezometer D-87 did not respond even after evacuation by compressed air, so it was bailed and surged to ensure that it was functioning properly. Piezometers were installed at shallow depths (designated "S" and screened near the water table elevation), deep depths (designated "D" and screened near the bedrock surface), or intermediate

depths (designated "I"). Depths were determined considering depths of nearby existing piezometers so that the entire saturated thickness of the aquifer could be monitored. Because the depths of many of the shallow and intermediate piezometers were close to each other, data from the shallow and intermediate piezometers were all used together for contouring the water table.

Presence and depth of free water was noted on boring logs during drilling, when possible, and water levels in borings and piezometers were noted immediately after installation and at various times thereafter. These water levels, along with water levels from existing monitoring wells, are tabulated in Appendix C of this report. A surface water monitoring point (SMP-4) was placed in the drainage ditch along St. Charles Rock Road at the northern tip of the site. Throughout most of the year, the water table in the aquifer is above the bottom of the ditch, so monitoring surface water elevations there provides data on hydraulic head in the aquifer. SMP-4 was destroyed before its location and elevation were surveyed but changes in water levels were recorded for three months.

During the preliminary phase, in-situ hydraulic conductivity was determined in four piezometers using a single-pulse bailer test, performed according to methods described by Hvorslev (1951). An air compressor was used to evacuate the piezometers, and water levels were measured as the well recovered. Data from these tests along with calculations of permeability using Hazen's formula are presented in Table D-1 in Appendix D of this report.

WST2.HYI II-3

C. DRILLING AND SOIL TESTING

The soil borings were drilled using a truck-mounted Acker MP-5 drill rig. Generally, 4-inch-diameter continuous-flight augers were used to drill above the water table and 4-1/2-inch-diameter Tri-cone rotary wash methods were used below the water table. The drilling was performed by Wabash Drilling Company (Subsurface Construction Company), St. Louis, Missouri, under the continuous observation of a Burns & McDonnell geologist who logged the encountered soil and rock materials. Surveying to determine boring elevations was done by Bollinger Surveying Company.

Laboratory testing of the soils material was performed by Kansas City Testing Laboratory, Shawnee Mission, Kansas. Tests included (three) moisture contents, (three) dry unit weights, (two) Atterberg limits, (eight) sieve analyses, and (two) hydrometer analyses. All tests were performed in accordance with ASTM standards.

The results of all soils laboratory tests for engineering properties are included in Appendix D.

D. GROUNDWATER SAMPLING AND CHEMICAL ANALYSIS

1. SAMPLE LOCATIONS

For the evaluation of groundwater chemical quality, 18 existing monitoring wells were selected for sampling. The wells were located in various locations around the site of the previously landfilled areas and

II-4

screened in the shallow, intermediate and deep parts of the alluvium. There were two sampling rounds, from December 11 to December 15, 1985, and from May 19 to May 21, 1986. The purpose was to evaluate the difference in groundwater quality in relation to seasonal variation. The sampled monitoring wells were as follows:

s-51	D-87
I - 59	D-88
I-66	D-89
s-80	D-90
D-81	D-91
D-82	D-92
D-83	D-93
S-84	D-94
D-85	D-95

It should be noted that Piezometer I-66 was not sampled during the first sampling round because it was inundated by surface water in the road-side ditch.

2. FIELD METHODS

All samples were collected by a Burns & McDonnell Environmental Engineer with assistance from West Lake employees.

Before sample collection, the water level was measured to determine the amount of water in the piezometer casing. Approximately three casing volumes were then removed from each piezometer with a bailer and the piezometer was allowed to recharge before sampling. A Teflon bailer with polypropylene rope was used to flush and sample.

WST2.HYI II-5

Before moving to the next well, the bailer was thoroughly cleaned with distilled water and the polypropylene rope was replaced.

The samples were collected in bottles prepared and supplied by the laboratory. The volatile samples were collected first, leaving no air space in the sample vials. All preservatives were added to the samples in the field except for the metals samples. Preservative was added to the metals samples after they were filtered through a 45-micron Geotech backflush filter. This took place at the end of each sampling day.

All samples were kept cool until delivery to the laboratory. All sample bottles were accompanied by Chain-of-Custody forms listing information such as the sample number name of sampler, date, bottles, and type of analysis.

3. CHEMICAL ANALYSIS

All samples were analyzed for priority pollutants listed under 40 CFR, Part 122. The priority pollutants consist of the following:

Volatile Organics Acid/Base Neutral Extractables Pesticides/PCB's Total Phenols Total Cyanide Metals

In addition, during Round 1, samples for Monitoring Wells D-83, S-84, D-85 and D-92 were analyzed for gross alpha and beta radiation. On May 7 and 8, 1986, water samples were collected from 32 wells by Department of Energy personnel and analyzed for gross alpha and beta radiation.

4. LABORATORIES

The priority pollutant samples collected during Round 1 were analyzed by Environmental Trace Substances Research Center, located in Columbia, Missouri. The samples analyzed for gross alpha and beta were sent to Controls for Environmental Pollution, Inc., in Santa Fe, New Mexico. Volatile organics were analyzed according to EPA Method 624. Base-Neutral Extractables were analyzed according to EPA Method 625. Acid extractables were analyzed according to EPA Method 604. Pesticides and PCB's were analyzed according to ERA Method 608. Metals were analyzed by inductively coupled plasma, and cold vapor atomic absorption was used to detect mercury.

The second round of priority pollutant samples was analyzed by Envirodyne Engineers of St. Louis, Missouri. The Department of Energy gross alpha and beta samples were analyzed by Oak Ridge Associated Universities, in Oak Ridge, Tennessee. Volatile organics were analyzed by EPA Method 624. Base-Neutral/Acid Extractables, and Pesticides/PCB's were analyzed by EPA Method 625. Arsenic, selenium, silver, antimony and thallium were analyzed by furnace atomic absorption. Mercury was analyzed by cold vapor atomic absorption. The remainder of the metals were analyzed by inductively copyled plasma.

WST2.HYI II-7

E. DATA INTERPRETATION

1. GEOLOGICAL INFORMATION

The geological and subsurface information obtained from the test borings on the site is illustrated on several subsurface profiles to facilitate interpretation and understanding of the geology of the site. The profiles have been used to show the lateral changes in subsurface materials, determined from the geologist's logs and soils laboratory data.

2. WATER LEVEL DATA

Selected rounds of water level measurements have been contoured in plan view to illustrate the configuration of the water table in different parts of the site at times of different river stage. From the water level contour maps, directions of groundwater flow are indicated. Maps were prepared separately for the deep piezometers so that comparison between groundwater flow in the deep and shallow/intermediate zones in the aquifer could be made. Note that the depths of the bottoms of the piezometers designated shallow and intermediate are vary nearly the same, so for purposes of this report, they are contoured together. Selected water levels are also shown on geologic profiles (Figures I-1 and I-3) to illustrate the relationship between deep and shallow water levels. In addition, two graphs are provided showing change in Missouri River stage relative to changes in water levels in selected piezometer.

* * * * * *

II-8

PART III

SUBSURFACE CONDITIONS

A. UNCONSOLIDATED OVERBURDEN

There are basically two types of unconsolidated overburden in the West Lake vicinity; windblown silt (loess) and Missouri River alluvium. The loess overlies bedrock on the bluffs bordering the Missouri River Valley. The old landfill operations on the West Lake property are generally to the west of the loess bluffs. No loess was encountered in test holes drilled for this investigation. Due to the long-term construction activities at the site, soil and crushed rock fill material occurs to depths of over 30 feet in some places on the site. An example can be seen on the log of Boring D-92, where fill soil and rock occurs to a depth of 31.0 feet.

Within the Missouri River Valley are thick deposits of alluvium. The alluvium consists generally of sand and gravel, with minor seams and lenses of clay and silt. Silt and clay occurs in the alluvium in significant amounts at shallow depths, with the maximum depth of occurrence of approximately 25 feet in some locations, and as little as approximately 5 feet in other areas. The alluvium extends to depths of over 100 feet. The alluvium thins abruptly toward the valley edge as the bedrock rises beneath it to form the valley wall. Permeability of the alluvium ranges from 2.4 x 10^{-4} cm/sec to 2.5 x 10^{-1} cm/sec (see Table D-1 in Appendix D).

Ten borings drilled for this investigation penetrated the full thickness of alluvium. Table III-l presents a summary of alluvium thicknesses and the

WST3.HYI III-1

depth to bedrock in each of these borings. All ten of these borings terminated in limestone bedrock.

Table III-1
SUMMARY OF BORING DEPTHS

	Thickness	Depth to
Boring No.	of Alluvium (ft(Bedrock (ft)
D-83	115.3	115.3
D-85	61.5	83.5
D-87	92.0	111.0
D-89	33.9	47.8
D-90	46.0	46.0
D-91	44.0	44.0
D-92	112.6	143.6
D-93	104.0	118.0
D-94	108.8	108.8
D-95	92.6	100.6

Natural deposition in the Missouri River floodplain has occured as the river channel meandered between the valley walls creating point bars and natural levees, filling abandoned channels, and temporarily forming swamps, lakes, and small channel environments. This resulted in the deposition of various materials throughout the floodplain, and, consequently, lithologic units terminate in the subsurface very abruptly both horizontally and vertically. A relatively consistent pattern in the alluvial profile is that coarse sands and gravels tend to occur lower in the profile and silts and clays occur nearer the ground surface. Soils that are predominantly silt and clay tend to occur in the upper 5 to 10 feet of the natural alluvium, but fines occur to depths of approximately 25 feet in places. This is generally above an elevation of 430 feet. A few seams of fine-grained soil occur below the 430-foot elevation as in Boring D-81. South of the site, a substantial

III-2 WST3.HYI

thickness of silty clay was encountered during the investigation. Boring D-91 encountered a deposit of silty clay to a maximum depth of 31.0 feet.

Between elevations of roughly 450 feet and 400 feet, the alluvium is characterized by interbedded seams of sand, silty and clayey sand, and a few silty clay seams. These seams range in thickness from a few inches to over 10 feet. They are quite discontinuous laterally as evidenced by the poor correlation between adjacent borings. This material is generally of a lower permeability than the underlying sands and may be considered an aquitard in the areas where the fines occur. Flow occurs through the soil, but transmission is impeded by the presence of a significant amount of fines. This zone is of a highly variable thickness due to its depositional history (see Figure I-3). In places, the bottom of the old landfill apparently extends below this fine grained stratum into the aquifer sands below.

Below an elevation of roughly 400 feet, thick deposits of sand which are quite uniform in character, are predominant. Several borings encountered gravel seams. For example, Borings D-81, D-92, D-93, and D-95 encountered gravel seams at depths ranging from 47 to 123 feet. While being more uniform in character than the overlying alluvium, these deeper sands exhibit changes in lithology and grain-size characteristics when correlated between borings.

B. BEDROCK

Bedrock was encountered in Borings D-83, D-85, D-87, D-89, D-90, D-91, D-92, D-93, D-94 and D-95. The rock was penetrated from 0.0-feet to 1.2 feet in these borings. The bedrock is described as a cream to light-brown limestone, medium strong to strong, and correlates with the St. Louis and Salem limestones observed in the West Lake quarry. The bedrock below the alluvium is apparently only slightly weathered as evidenced by the difficulty with which it was penetrated. A few fracture zones are visible in the quarry but the limestone is predominantly unfractured. Very few seeps discharge into the quarry which has been excavated to more than 180 feet below the alluvial water table.

Table III-2, below, lists the borings in which bedrock was encountered and the depths and elevations of the bedrock surface, which was found to be limestone in all cases.

Table III-2

	Depth to	Elevation
Boring No.	Bedrock	of Bedrock
D-83	115.3	329.1
D-85	83.5	369.4
D-87	111.0	349.0
D-89	47.8	406.3
D-90	46.0	400.0
D-91	44.0	404.0
D-92	143.6	331.77
D-93	118.0	332.70
D-94	109.8	333.88
D-95	100.6	352.49

The base of the nearby quarry is in shaley limestone, probably of the Warsaw Formation, which is at an elevation of about 240 feet. The St. Louis and

Salem limestones in the quarry area extend from near the ground surface down to the Warsaw Formation.

C. GROUNDWATER OCCURRENCE

1. GENERAL DESCRIPTION

Groundwater in the alluvium generally occurs as a single aquifer under water table conditions. There are a few localized exceptions to this condition which cause minor and usually temporary confining conditions. Another minor exception that has been found is that the water level in piezometer S-80, at the south end of the site represents a perched water table above a localized silt and clay deposit. The water table surface is quite level, not varying more than a foot or two in elevation over most of the site at any given time; thus the gradient is very low.

The water table elevation fluctuates vertically as much as 7 feet, in any particular well, throughout the year in response to variations in precipitation. Precipitation affects the Missouri River stages, infiltration on the site, and some localized recharge due to runoff from the river valley bluffs; all of which have direct affect on the water table elevations.

Generally, the major portion of the aquifer is responding to a gradient induced by the configuration of the Missouri River bedrock channel and also influenced by the Missouri River stage (Ref. 3). but superimposed upon this general gradient are some minor groundwater mounds and

WST3.HYI

depressions which influence the gradient near the water table surface. These are apparent from groundwater contour maps, several of which were constructed from water level data obtained from this study. The August 29-30, 1984 data are representative of the perennial contour pattern and are shown on Figure III-2. The most prominent of the water table features is the persistent mound occurring in the southern portion of the landfill.

The water table gradient is variable with time in different parts of the aquifer, although these variations are of a relatively minor scale. Since the water table is nearly level, a relatively minor change in the water level in an area can cause a change in flow direction at the water table surface. Because of the many minor effects on the water table over the area, such as local recharge and discharge areas and variable soils materials, the water table is an uneven surface at any given time and may change its configuration over a period of time. However, overall movement of groundwater over a substantial period of time is most often to the northwest, either toward the river or subparallel to the river.

The elevation of the water table at the site generally fluctuates between 430 and 440 feet during the year. The water table is high during and after the spring rains and snowmelt of March and April and rises slightly after the fall rains in October (see Figures III-2 and III-3). The water table fluctuations generally mimic the Missouri River stage fluctuations in a subdued manner.

III-6 WST3.HYI

At any given time, the water table is nearly level with the notable exception of the persistent groundwater mound in the vicinity of Piezometers S-75, S-76, I-73 and D-89 which is discussed later in this section. In the northern half of the landfill site, the relief on the water table surface is commonly less than 0.5-feet at any given time, indicating a very low gradient. The groundwater mound in the southern portion of the landfill is seen to exhibit relief of from 1 to about 4 feet at the different times of observation for this study.

At times, there is an apparent predominantly downward component of flow in the aquifer near the valley wall. This is indicated by the difference in hydrostatic head between piezometers screened in the upper and lower portions of the aquifer. The deeper piezometers generally indicate lower water levels than nearby shallower piezometers. groundwater flows from areas of higher pressure to lower pressure, the flow would be generally downward in this area. An example of this is seen when comparing October 1984 water levels in the deeper D-81 and D-89 piezometers to water levels in the shallower S-75 and S-76 piezometers. The calculated vertical gradient near the valley wall? varies somewhat throughout the year but generally ranges between 0.117 0.0007 This vertical component of flow dominates the horizontal component near the valley wall, which generally ranges between 0.003 and 0.008 throughout the year. Further west, away from the sloping bedrock valley wall, flow is predominantly lateral. Comparison of hydrostatic head in D-83 with shallow hydrostatic head in I-62 indicates little elevation difference and, therefore, almost no vertical component

Unis

WST3.HYI III-7

w.to?

of flow exists. The flow is basically horizontal; generally toward the Missouri River. The horizontal gradient generally ranges between 0.0003 and 0.0007 throughout this year as calculated from regional groundwater contours (obtained from Earth City piezometers as shown on Figure IN-1).

Generally, the water table elevation is influenced most significantly by the stages of the Missouri River. As the river rises or declines, the water table responds similarly but in a delayed and subdued manner. Hydrographs were constructed from piezometers which exhibit the typical pattern of change in water levels throughout the year. As can be seen these hydrographs with the Missouri River stages comparing (Figures III-2 and III-3), the water levels in the piezometers are seen to rise steadily in the spring, when the river is rising, and decline during the drier summer months. the rise in the water table at the West Lake site lags behind the overall rise in the river stage during the spring by several weeks. The alluvium creates a buffer zone between the river and the alluvial groundwater beneath the site causing the time lag. Another effect of the alluvium is to decrease the effect of rapid changes in the river stage so that the water levels in the piezometers do not fluctuate dramatically on a daily basis. This lack of daily fluctuation of the water table was documented by the continuous water level recorder, which reveals gradual, slow changes in water table elevation.

The water table generally slopes downstream and toward the river during the dry summer months and generally downstream during the wet spring

III-8

WST3.HYI

?? whotau they had

months, although changes in gradient direction apparently occur at other times during the year in response to changes in stage of the Missouri River. Determination of this overall gradient direction is based upon Earth City piezometer readings and from water table contour maps of the floodplain across the Missouri River Valley from the site (Ref. 4) (see Figure IN-1). The gradient may be away from the river for short periods of time during high river states, but this is apparently only a localized affect near the river.

The unconfined condition of the aquifer is evidenced by the absence of a correlated between borings. continuous aquiclude being indication of unconfined conditions is the water level data from clustered piezometers. As can be seen by comparing Figures III-1 and III-4, five clusters (pairs) of piezometers, S-84 and D-85, I-66 and D-94; I-62 and D-83; S-82 and D-93; S-51 and D-90; and I-50 and D-91 show essentially no elevation difference in water levels between the piezometers screened in the deeper portion of the aquifer and the adjacent piezometers set to shallower depths. This indicates that the these measurements were made.

Another cluster, S-80 and I-50, exhibits significant, though not large, water level differences between adjacent deep and shallow wells. The difference between water levels in S-80 and the deeper I-50 is due to a

shallow perched waer zone which is intercepted by the screened segment of Piezometer S-80. Piezometer S-80 indicates the head in the perched zone and I-50 indicates the head in a deeper sand seam. The san seam is confined below silty clay. Because the water elevation in I-50 is very nearly the same elevation as in nearby wells and since the clay seams in the vicinity tend not to be laterally extensive, it is concluded that the groundwater in I-50 is semi-confined, rather than completely confined. That is, it has some degree of hydraulic connection with the surrounding groundwater, but is partially confined because of the presence of the overlying low-permeability material. Since the water table in Piezometer S-80 is perched, the water levels from this well are excluded from the groundwater contour maps.

Water levels were continuously monitored in Piezometer I-62 from May 24 to October 23, 1984 using a Stevens water level recorder. The water level remained fairly steady, with only minor fluctuations, until approximately July 6, 1984 when a fairly steady decline from 436.1 to 435.6 occurred until about the end of July. Another more rapid decline in the water level occurred from about August 6 to August 28 when the water elevation dropped from 435.4 to 432.9. The water level remained fairly steady through September until October 3 when the recorder was removed. The indication from the continuous monitoring data is that monthly water level measurements are adequate for detecting any significant changes in water table elevations.

III-10 WST3.HYI

FLOW DIRECTION AND GRADIENTS

Figure III-1 includes water table contours and arrows indicating general groundwater flow direction. It is important to note that the map was made using water level data from August 29 and 30, 1984, and that the pattern of contours is consistent with the pattern from the other water well measurements made for this study, thus, the pattern of water table contours is relatively constant throughout the year, even while the elevation of the water table in the entire aquifer is illustrated by the water levels shown on the detailed geologic profile across the site (Figure I-3).

To determine the difference between groundwater flow in the upper portion of the aquifer as compared to that in the lower part of the aquifer, a comparison was made between water levels measured in the shallow and intermediate piezometers and those measured in the deep peizometers.

The deep and shallow flow patterns are generally similar, but there are times when the hydraulic gradients in the lower part of the aquifer are extremely low (less than 1 foot per mile), and the groundwater flow rates in the deep aquifer are negligible. This can be seen by comparing Figure III-4 (where the flow patterns and gradients in the upper aquifer are similar to the general pattern shown on Figure III-3), with Figure III-5, where the gradient is negligible, but very slightly elevated in the northern parts of the landfill. Figures III-5 and III-6 have been provided to illustrate that there are times when a gradient builds up on

WST3.HYI III-11

the hydraulic head in the deep aquifer, in response to recharge from the surface water recharge zones in the southeast part of the site. The changing pattern of hydraulic head distribution in the deep portion of the aquifer is also probably related to changing pressures in the aquifer canal by rise and fall f river stage. As can be seen in Figures III-6 and III-7, the pattern of groundwater flow in the deep aquifer is similar to that in the shallow aquifer.

The flow direction of groundwater beneath the West lake site is dependent upon which part of the aquifer is considered. At the surface of the water table, a perennial mound in the southern portion of the site controls the flow direction (see Figure III-1). Groundwater in the upper portion of the aquifer will flow away from the mound to the north, west, and south. Because this mound is small (less than 3 feet of relief in comparison to the thickness and volume of the aquifer, it has only a slight affect on groundwater flow direction at greater depths. The groundwater mound is the result of a local recharge area created by: (1) the pumping of water from the quarry to surface drainage ditches which is discharged to this area, (2) surface infiltration along Old St. Charges Rock Road, and (3) possible leakage from unlined surface water holding ponds in the quarry vicinity. Groundwater in the lower portion of the aquifer flows generally in a westerly or northwesterly direction in response to the gradient induced by the Missouri River stage and the gradient of the river valley. Flow is predominantly downward near the valley wall. Another influence on the flow direction is the nonuniform permeability characteristics of the aquifer. Because

(

III-12

WST3.HYI

of the various alluvial materials, such as clay lenses and small sandfilled channels, groundwater will flow more rapidly through the higher permeability materials. These effects will tend to be localized and will not change the overall flow direction drastically.

In the northern part of the site where the water table gradients are seen to the very low (see Figure III-1), groundwater flow is generally northward near the northern end of the site and westward from the western portion of the landfill. Thus, flow is generally radiating from the central portion of the landfill toward the perimeter, probably due to slight mounding of the water table within the landfill itself. Because of the extremely low hydraulic gradients and low relief on the water table, this pattern may not be consistent with time; local variations may alter the pattern somewhat, but these variations are minor. Thus the pattern shown on Figure III-1 predominates throughout the year.

2. GROUNDWATER QUALITY

WST3.HYI

a. Distribution of Chemical Constituents

The lateral and vertical distribution of detected chemical constituents was investigated to determine if the landfill was affecting local and downgradient groundwater quality.

(1) Lateral Distribution: Chemical results were obtained from wells upgradient, downgradient, and around the perimeter of the

III**-**13

More

landfilled area. When chemicals were detected at several locations, the results were plotted on a site map. The most informative chemical distribution maps are shown in this report.

The complete results of chemical analysis are contained in Appendix E.

The only priority pollutant volatile organic compound detected in both rounds methylene chloride. The chemical was distributions for Round 1 and Round 2 are shown on Figures and . In Round 1, methylene chloride was detected in wells throughout the landfill area. Piezometer D-90 showed 83 ug/l of methylene chloride, the highest detected level. concentration pattern was irregular and therefore not contoured. In general, the downgradient wells showed lower levels of methylene chloride (from 6 to 12 ug/1), except Piezometer D-83, which had 55 ug/1. *Acetone, not a priority pollutant, was also detected in most samples. Methylene chloride was also detected in Round 2, but at only three locations and at lower concentrations. Piezometer D-90, only 6 ug/1. Piezometer D-89 contained showed 10 ug/1Piezometer I-59, a shallow downgradient well, showed 7 ug/1. The rest of the well concentrations were less than the detection limit of 5 ug/l.

The only priority pollutant base-neutral compounds detected in Round 1 were bis(2-ethylhexyl)phthalate and trace amounts of two

III-14 WST3.HYI

other phthalates. Only bis(2-ethylhexyl)phthalate was detected during Round 2 at one location. The chemical distribution map for Round 1 is shown on Figure III-10. Round 1 results showed bis(2-ethylhexyl)phthalate at five locations throughout the landfill area. The pattern was irregular and therefore not 115 ug/1, contoured. Piezometer D-90 showed while the background wells had concentrations less than the Piezometer D-92 had the highest level of detection limit. 477 ug/l. The downgradient well mostly had concentrations either close to or below the detection limit.

Round 2 results showed bis(2-ethylhexyl)phthalate at only one location. As in Round 1, Piezometer D-92 had the highest level of 25 ug/l. All other wells showed concentrations less than the 10 ug/l detection limit.

The Round 1 results, in addition to providing priority pollutants concentrations, also provided information on possible additional organic compounds. Trace amounts of aliphatic hydrocarbons (also identified as diesel oil) were detected in Piezometer I-59 and S-80. An organic odor was evident in Piezometer S-80 during both sampling rounds. Most of the samples contained a variety of tentatively identified compounds such as phthalate esters, trimethyl cyclohexane-1-one, and other compounds found in plastics. The source of these compounds is unknown.

III-15

Phenol was detected at five locations in Round 1. Figure III-11 shows the distribution of phenol. The pattern is irregular and therefore not contoured. Piezometer D-92 had the highest concentration of 19 ug/1. The downgradient wells to the west of the landfill had concentrations of up to 7 ug/1. The detection limit was 1.7 ug/1.

Phenol was not detected in Round 2 above the detection limit of 10 ug/1. No other acid-extractable compound was detected. A general analysis of total phenolic compounds, a different analysis with detection limit of 2 ug/1, was negative.

Trace amounts of several pesticides were detected Round 1. Compounds detected included gamma BHC (Lindane), delta BHC, chlordane, dieldrin, endrin, 4,4' DDD, 4,4' DDE, 4,4' DDT, hexachlorobenzene. The compounds DDD and DDE are and decomposition products of DDT. All wells tested positive for at least one pesticide. Piezometers S-82 and D-83, to the west of the landfill, showed the greatest numbers and highest concentrations of pesticides. All pesticide concentrations were less than 0.70 ug/l. The distribution of two frequently found pesticides, chlordane and 4,4' DDE, were plotted and shown on Figures III-12 and III-13. Chlordane was not detected in the upgradient wells, and shows an irregular pattern in the downgradient wells. Piezometer S-82 had a maximum concentration of 0.258 ug/1. The DDT decomposition product, 4,4' DDE, was

III-16

WST3.HYI

found at 11 wells, both upgradient and downgradient of the landfill. The upgradient and background wells had higher concentrations. Piezometer D-89 had the maximum concentration at 0.117 ug/1. In general, the distribution of pesticides is irregular and the source is unknown. No pesticides were detected in Round 2. The detection limits in Round 2 were similar to those in Round 1.

elaboration protection

The distribution of inorganic constituents followed an undefined pattern as did the organic constituents. Total cyanide was detected at 1 or 2 ug/l levels at six locations during Round 1. The highest level was 6 ug/l at Piezometer D-90 to the south of the landfill area. In Round 2, total cyanide was detected in only one well above the 5 ug/l detection limit. Piezometer D-89 had the highest level at 7 ug/l. Furth ground will be the figure of the south of the highest level at 7 ug/l.

The Round 1 metals ICP (Inductively Coupled Plasma) scan produced results for 32 dissolved metals. Conventional parameters such as iron and sodium were plotted to determine a pattern with respect to the landfill, since these compounds are often associated with landfill contamination. The distributions of sodium and iron are shown on Figures III-14 and III-15. The sodium concentration ranged from 5 mg/l to a high of 175 mg/l at Piezometer D-83. The ranges were generally between 30 and 70 mg/l both upgradient and downgradient of the landfill, with no distinct pattern. Levels were generally higher in the wells

west of the landfill (over 100 mg/l. Dissolved distribution was also irregular. The highest concentration of 31.5 mg/l was found in Piezometer S-84. Levels were generally landfill within the boundary. Downgradient higher concentrations were slightly higher than upgradient concentrations.

In Round 1, very few priority pollutant metals were detected, except for copper and zinc. The distribution of zinc, which was found in almost all wells, is shown for Rounds 1 and 2 on Figures III-16 and III-17. The concentrations ranged from less than 2 ug/1 in Piezometer D-90 to 1240 ug/1 in the adjacent Piezometer S-51. Most other concentrations ranged from 30 to 140 ug/1 throughout the landfill.

In Round 2, the detection limits for most metals were approximately one tenth the detection limits in Round 1. Even at detection limits of 1 to 4 ug/1, very few heavy metals were detected. The highest lead concentration was found at Piezometer D-91, to the south of the landfill. Compounds such as antimony, nickel, thallium, and zinc were commonly found. Silver was detected but at levels close to or below the detection limit of 2 ug/1. The distribution of zinc is shown on Figure III-19. As in Round 1, the lowest level of less than 2 ug/1 was found in Piezometer D-90, while the highest level of 2000 ug/1 was found in the adjacent Piezometer S-51. The

III-18

WST3.HYI

remaining wells ranged between less than 2 and 70 ug/l throughout the landfill.

The distribution of the heavy metal arsenic was plotted, since several positive values were obtained. This is shown on Figure III-18. Piezometer D-91, a background well, contained 4 ug/l of dissolved arsenic. The maximum level of 9 ug/l was found in Piezometer S-84 and S-88.

Generally, the distribution of dissolved metals showed no distinct pattern and downgradient levels did not significantly differ from upgradient levels.

The significance of the chemical constituent concentrations will be discussed in Part IV.

In addition to priority pollutant analysis, four wells were also sampled for gross alpha and beta radiation during Round 1. The results are included in Appendix E. The values for gross alpha ranged from less than 2 pCi/l (pico curies per liter) in Piezometer D-83 to 270 pCi/l in Piezometer S-84. Piezometer S-84 had the only gross alpha or beta level exceeding 31 pCi/l. The laboratory explained that these high levels could have been due to the presence of suspended clay material in the sample, and that future samples should be filtered.

III-19

In May, 1986, 32 well samples were collected and analyzed for gross alpha and beta by the Department of Energy. The results are included in Appendix E. Further isotopic analyses are being performed on many of the samples.

- (2) <u>Vertical Distribution</u>: The vertical distribution of chemical constituents was evaluated to determine:
 - (a) The presence of chemicals in the shallow and deep aquifers.
 - (b) Differences between the shallow and deep aquifers with respect to chemical constituents.

Organic chemicals were detected both in the shallow and deep part of the aquifer. In general, highest levels of methylene chloride were found in the deep piezometers, although only three piezometers had detectable levels in Round 2. Bis(2-ethylhexyl)phthalate was only found in deep piezometers in both Round 1 and Round 2. In Round 1, phenol was found in both shallow and deep piezometers. Pesticides were also found in both shallow and deep piezometers at similar concentrations.

Dissolved metals concentrations showed no definite pattern with respect to shallow and deep aquifer levels. In some well clusters, sodium was highest in the deep wells and in other well clusters sodium was highest in the shallow wells. The same was

true for iron, zinc and many of the other detected metals. The well cluster of D-90 and S-51 consistently showed a low zinc level in the deep well and a high zinc level in the shallow well. The reason for this is uncertain, since this occurrence was inconsistent with other metals data but nonetheless is not at a level of concern.

b. Seasonal Variation

The sampling rounds occurred during two distinct seasons. took place in December while Round 2 took place in May. In general, more chemicals were detected in Round 1, and higher concentrations. Among those chemicals found to a greater extent in Round 1 were methylene chloride, bis(2-ethylhexyl)phthalate, phenol and pesticides. Priority pollutant metals were found more often in Round 2 because of the lower detection limits. Comparable metals such as zinc did not show substantial changes from Round 1 to Round 2.

c. Validity of Data

The validity of the chemical data is dependent on:

- o The field collection of the water samples and proper preservation of the samples.
- o The chemical laboratory quality assurance/quality control (QA/QC).

WST3.HYI III-21

The organic data can be evaluated using the laboratory spike and blank and replicate sample data. During Round 1, the spike and duplicate sample results were within method accuracy limits. Bis(2-ethylhexyl)phthalate was detected in the blank at 3.5 ug/l.

The Round 2 laboratory volatile organic blanks contained 17 and 15 ug/1 of methylene chloride. Trace concentrations of bis(2-ethylhexyl)phthalate were detected in the blanks.

The QA/QC information provided by the laboratories for Round 1 and Round 2 indicates that the sample data is reliable with respect to laboratory analysis. Possible interferences are methylene chloride and bis(2-ethylhexyl)phthalate. The Round 2 blank concentrations of methylene chloride may be high enough to cancel out the concentrations found in the three wells.

Field procedures could also have introduced an error factor to the chemical results. Common sampling errors are:

- o Introduction of surface contamination to the sample.
- o Improper cooling, storage and preservation.
- o Aeration of sample during collection.
- o Insufficient purging of stagnant well water.
- o Use of unclean sample bottles and sampling equipment.

Since precautions were taken to minimize these errors, the collected samples are probably representative of the aquifer water quality.

III-22 WST3.HYI

It should be noted that the Department of Energy samples, taken on May 7 and 8, 1986, were sampled by different personnel. The quality control of the filed procedures are unknown.

* * * * *

III-23

PART IV

IMPACT OF LANDFILL ON GROUNDWATER QUALITY

A. DOWNGRADIENT WATER USE

As described above in the discussion of regional groundwater hydrology, the discharge point for the groundwater downgradient beneath the old landfill site is the Missouri River. There are no water supply wells at the Earth City industrial park, and no known water supply wells elsewhere downgradient. The drainage ditches along St. Charles Rock Road intersect the water table. Therefore, the groundwater underflow beneath the site passes through the ditches as a surface water occurrence.

B. DOWNGRADIENT GROUNDWATER QUALITY

To assess the impact of the landfill on groundwater quality, the chemical constituent levels in the background wells were compared with levels within and downgradient of the landfill.

Methylene chloride was found in a background piezometer (D-91), an upgradient piezometer (D-89) and is also a possible laboratory interferent. It is unclear whether the landfill is a source of methylene chloride.

Bis (2-ethylhexyl)pthalate was found in an upgradient (D-89) and is a possible laboratory interferent. Levels in Round 1 were generally highest within the landfill (D-92), and may therefore be affected by the landfill.

Phenol was found at its highest levels within the landfill area (D-92) and in downgradient piezometers and could therefore be affected by the landfill.

The various pesticides found in Round 1 showed no particular distribution pattern. Some were found more in the background wells (4, 4'DDE) and others in the downgradient wells (heptachlor, chlorodane). Levels tended to be highest in Piezometers S-82, D-83 and S-84, all downgradient. The effect of the landfill on pesticide levels is unclear, since none were detected in Round 2.

As mentioned earlier, the distribution of dissolved metals showed no particular pattern. Sodium levels tended to be higher in the interior and downgradient wells, as did iron levels. Other metals of concern did not appear to be affected by the landfill.

The chemical results suggest that certain wells showed relatively high levels of several constituents. During Round 1, Piezometer D-90 had the maximum concentrations for methylene chloride, total cyanide and also contained bis (2-ethylhexyl) pthalate. Piezometer D-92 had the maximum concentration of phenol and bis (2-ethylhexyl) pthalate and also contained methylene chloride.

During Round 2, Well D-89 had the maximum concentration of methylene chloride and bis (2-ethylhexyl) phthalate. One possible source is the vehicle maintenance shop located near piezometer D-89.

IV-2

WST4.HYI

C. RISK ASSESSMENT

1. POTENTIAL PATHWAYS

The potential pathways of chemical transport from the landfill are the following:

- o Direct contact.
- o Air transport.
- o Surface water runoff.
- o Groundwater transport.

Direct contact and air transport would primarily affect persons working in and around in the landfill operation and were not considered major pathways. The risk is most likely similar to operations at most municipal landfills.

Surface water runoff from the landfill primarily flows to a drainage ditch along the north side of the landfill and the south side of St. Charles Rock Road. This ditch is also occasionally recharged with groundwater. This surface water either recharges the groundwater or discharges to the Missouri River. A pond along this ditch is located on the northwest side of the landfill, and is known to contain fish. Groundwater could potentially be affecting fish in this pond, but more data is needed to evaluate this possibility. Surface water runoff to the south and southwest flows out across relatively flat agricultural

WST4.HYI

level, and some of this runoff may join the small intermittent creeks which traverse the area.

The groundwater pathway would affect persons using groundwater downgradient of the landfill before it discharges in the Missouri River.

As discussed in Part IV, Section A, no private wells have been identified. The remote possibility of future wells being located down gradient of the site should be considered when evaluating the groundwater quality.

STATE AND FEDERAL WATER QUALITY CRITERIA doungt dien To

The concentration levels of various groundwater chemical constituents found during this investigation were compared with Federal and State drinking water quality standard and recommendations. The comparison is shown on Table IV-1. The compounds listed were the major detected compounds which have water quality standards and recommendations. The maximum, or worst case, concentrations were used to evaluate the groundwater quality.

According to the available data, most of the chemicals detected in the groundwater were at levels below drinking water quality limits and guidelines. Exceptions are phenol, chlordane, 4,4' DDT and cyanide.

Phenol was considerably below federal guidelines for health and aesthetics (taste and odor) but was greater than the drinking water limit of 1 ug/1. Chlordane was detected and therefore exceeded the

proposed RMCC of 0 for potential carcinogens. The EPA Health Risk Criteria for 4,4'DDT is 0.00024 ug/l and was detected at 0.051 ug/l. Some decomposition products, 4,4'DDE and 4,4'DDD, were also detected. Total cyanide, at 7 ug/l exceeded the drinking water standard of 5 ug/l; however, the standard is based on cyanide amenable to chlorination. Arsenic, at 9 ug/l, exceeded the EPA Health Risk criteria for one in 100,000 cancer risk but was below the 50 ug/l drinking water standard.

WST4.HYI

PART V

CONCLUSIONS

A. SUMMARY OF HYDROGEOLOGICAL CONCLUSIONS

Based upon information from the Burns & McDonnell investigation of the West Lake Landfill site it can be concluded that:

The alluvium of the Missouri River forms the major aquifer in the vicinity of the site. The underlying bedrock is relatively impermeable, both on the valley side slopes and the bedrock valley floor buried beneath the alluvium.

Alluvial deposits of the Missouri River are in hydraulic communication with the river, thus the river has a major influence on water leves in the alluvium. A rise in river stage during seasons of high rainfall and snow melt causes the water table in the aquifer to rise. Conversely a seasonal drop in the river stage causes the water table in the aquifer to drop. Although the rise and fall of the aquifer is less than that of the correlative change in river stage, the change in water table elevation is relatively uniform throughout the entire extent of the aquifer in the site vicinity.

The predominant direction of groundwater flow in the aquifer in the region near the site is northwestward toward the Missouri River. This predominant, regional pattern of flow is illustrated on Figure IN-1, which was made using water levels in piezometers in the Earth City area in 1976. There are broad fluctuations in this flow direction throughout the year and the predominant

7

flow direction ranges from slightly south of due west to northwest (subparallel to the northerly flow direction of the Missouri River). During short periods of the year (primarily in the spring and for short periods in winter), when the river stage is rising rapidly, the predominant groundwater flow direction in the aquifer may be temporarily reversed in the localized vicinity of the river. This occurs while the river is at a higher elevation than the water table. This generally eastward flow is of short duration and is overshadowed by the predominant westward flow at some distance from the river.

Throughout most of its extent, the aquifer is generally unconfined (under water table conditions). Relatively low-permeability, discontinuous clayey and silty zones in the upper part of the alluvium may cause semiconfined and perched water conditions in very localized areas.

Other localized effects, of only minor significance, may affect groundwater flow directions in the aquifer. As can be seen on Figure III-1 the only local feature of note is a perennial groundwater mound, superimposed on the generally westward sloping water table which predominates on the rest of the site. The groundwater mound is located on the southern part of the West Lake site, and occurs due to a localized recharge zone. This mounding is created by: (1) water pumped from the quarry being discharged at the ground surface above the mound, (2) surface infiltration from the drainage ditches along Old St. Charles Rock Road after rainfall (illustrated by cross-hatching on Figure III-1, (3) and possible leakage from the surface water holding ponds immediately west of the existing quarry (also illustrated by

cross-hatching on Figure III-1. This mound generally affects flow direction only in the upper portion of the aquifer, but may result in a significant vertical component of flow beneath the mound. The mounding effect is superimposed on the effect caused by changes in river stages and the effect of the bedrock valley. In the bulk of the aquifer, other than beneath the mound, the vertical component of flow is insignificant.

In the area of the groundwater mound, flow direction in the upper portion of the aquifer is to the south, west and north away from the mound. Flow direction lower in the aquifer includes a major component that is vertically downward near the valley wall, but is horizontal either toward or subparallel to the Missouri River at some distance from the valley wall.

Gradients in hydraulic head in the lower aquifer are, at times, extremely low. See, for example, Figure III-5. Thus, minor fluctuations in head (in the range of 1/10-foot) may be sufficient to cause major changes in flow direction. But because the gradients are very low at such times, groundwater flow rates are negligible.

At other times (see for example, Figure III-7), there may be two to three feet of differential in hydraulic head across the site. The pattern in hydraulic head distribution in the deep aquifer at such times is seen to reflect approximately the same pattern as the head distribution in the shallow aquifer (see Figure III-4). Thus, the surface water features which recharge the shallow part of the aquifer and cause groundwater in the southeastern part of the site also recharge the deeper part of the

aquifer by vertical infiltration from above. During such times, groundwater flow in the deep portion of the aquifer is laterally, away from the recharge area, predominantly to the west and northwest. During all times of measurement, the hydraulic gradients in the deeper part of the aquifer were substantially less than that in the shallow part of the aquifer.

Piezometers D-89 and I-73 are in the upgradient portion of the site, in the vicinity of the predominant recharge area of the site. Piezometers I-50 and D-91 are in an area south of the landfill where they are outside the area of influence of the groundwater flow pattern of the site. Thus, the groundwater in the aquifer there is not downgradient of the site, but is recharged from elsewhere, and samples from these wells may be considered background water quality samples for the aquifer. The surface water drainage ditches along the northern edge of the site are interconnected with the water table, and are in the downgradient area of the groundwater flow pattern. Thus, they contain not only surface water runoff, but also underflow of groundwater from the aquifer.

Based on an interpreted value of hydraulic gradient of <u>0.003</u> across the site, (considering the fan-shaped flow pattern diverging from the groundwater around beneath the landfill), a value of <u>6.35*10**</u> cm/sec for hydraulic conductivity of aquifer materials, a saturated thickness of <u>95</u> feet, and a site perimeter length of <u>6900</u> feet, the flow rate is calculated to be <u>27000</u> gallons per day beneath the entire site. For an assumed value of <u>0.20</u> for effective porosity, the groundwater flow velocity is calculated to be <u>75</u> feet per year.

B. SUMMARY OF GROUNDWATER QUALITY

- Methylene chloride was the only detected priority pollutant volatile organic chemical. In Round 2, the detection of methylene chloride was accounted for by its concentration in blank samples.
- 2. During Round 1, methylene chloride had a maximum concentration in Piezometer D-90.
- 3. The compounds bis(2-ethyl hexyl) phthalate and phenol were found at the maximum concentration at Piezometer D-92 during Round 1.
- 4. The general distribution of organic constituents was scattered and irregular. In general, phenol and methylene chloride were found to be slightly higher in downgradient wells during Round 1. The landfill is a possible, but not certain, contributor.
- 5. The distribution of dissolved metals was irregular and significant differences were not detected between the background, upgradient and downgradient wells.
- 6. Many chemical constituents were detected in the deep wells but no significant increase was detected between the deep wells and the shallow wells.

- 7. More chemicals were detected during Round 1 (December 1985) at greater concentrations than during Round 2 (May 1986).
- 8. A variety of pesticides were detected during Round 1 at various locations, especially Piezometers S-82, D-83 and S-84. The source of these pesticides is unknown. W detection in Normal 2
- 9. Compared to state and federal drinking water standards, the levels of chemicals found in the groundwater do not appear excessive. Some of the pesticides, such as chlordane and 4,4' DDT, exceeded recommended levels.

 for cancer risk.
 - 10. Surface water and groundwater are connected in the drainage ditch running along the north side of the landfill. A pond connected to this ditch, located on the northwest side of the landfill, contains fish which could be affected by the groundwater.
 - 11. No water supplies using groundwater downgradient of the landfill have been found.

C. PROPOSED GROUNDWATER MONITORING PROGRAM

The purpose of the proposed groundwater monitoring plan is to evaluate the effect of the landfill on groundwater quality through long-term monitoring. Certain constituents detected during this investigation will also be resampled to clarify differing results between Round 1 and Round 2.

The components of the proposed plan are as follows:

1. SHORT-TERM MONITORING

The following piezometers will be resampled and analyzed for the listed constituents:

I-59: Volatile Organics

D-81: Volatile Organics

S-82: Pesticides

D-83: Volatile Organics

S-84: Pesticides

D-87: bis(2 ethylhexyl) pthalate

D-89: bis(2 ethylhexyl) pthalate, volatile organics

D-90: bis(2 ethylhexyl) pthalate, volatile organics

D-92: bis(2 ethylhexyl) pthalate, volatile organics

Based on this data, the long-term monitoring plan will be revised appropriately.

Also, because of the presence of fish in the surface pond to the west of the landfill, ,the fish should be sampled and analyzed for the following constituents:

Priority pollutant pesticides

Priority pollutant metals

gross alpha and beta radiation

From this data, a decision can be made on whether or not fishing should be allowed in this pond.

V-7

WSTCON.HYI

2. LONG-TERM MONITORING

e moni R

The following piezometers shall be sampled on a quarterly basis:

S-84, D-85: north of landfill

S-82, D-93: west of landfill

D-89: upgradient

D-91: background

D-92: within landfill boundary

The samples will be analyzed according to MDNR parameters for landfill monitoring. In addition, the water level will be measured in each well before sampling.

An analysis of the results will determine if future remedial action is needed at the site.

APPENDIX A

CRITERIA FOR LOGGING OF SOIL AND ROCK BORING LOGS

LEGEND AND NOMENCLATURE OF DRILLING LOGS

Information preceding the logs relates to pertinent project and boring descriptions, which are self-explanatory. Remaining items on drilling logs are described as follows:

- 1) <u>DEPTH</u>: Depth below a given reference elevation. Normally, units are in feet and are from the aforementioned ground surface, unless otherwise noted.
- DESCRIPTION: Description of soil or rock material according to Unified Soil Classification. Word descriptions give principal soil constituent, other minor soil constituents, color, moisture, consistency or density, plasticity, and other appropriate material characteristics. Geologic names, where appropriate, are shown in REMARKS. A solid line denotes a stratigraphic change, a dashed line indicates the approximate location of a stratigraphic change. Rock samples are described according to lithology, color, moisture content, weathering, strength, and any discernible structure. Criteria for evaluating weathering and strength (established by the U.S. Bureau of Mines,) are as follows:

Weathering:

FR: (Fresh) No visible signs of weathering.

SW: (Slightly Weathered) Weathering (alteration) limited to the surface of major discontinuities, no weathering of rock material.

MW: (Moderately Weathered) Weathering (alteration) extends throughout the rock mass, but the rock material is not friable.

HW: (Highly Weathered) Rock is decomposed and friable, but the rock texture and structure are preserved.

XW: (Extremely Weathered) Soil material with the original texture, structure, and mineralogy of the rock completely destroyed.

Strength: VS: (Very Strong) Rock surfaces cannot be scratched by a steel nail.

S: (Strong) Faint scratch made with a steel nail.

MS: (Moderately Strong) Distinct scratch trace made with a steel nail.

W: (Weak) Slight scratch left by fingernail, material can be gouged out with steel nail.

VW: (Very weak) Material can be gouged out with fingernail.

3) LOG OR CLASSIFICATION: Unified Soil Classification symbols are shown in reference to appropriate description of soil.

Rock material is noted by visual symbols (referenced from NAVFAC DM-7 Manual, March 1971, with slight revision) representing rock classification, as shown below:

	SANDSTONE		SILTSTONE
6.00°	CONGLOMERATE		MUDSTONE
	COAL		DOLOMITE
	LIMESTONE		CHALK
	COMPACTION SHALE		CEMENTED SHALE
	GNEISS	VIIII	SCHIST
	GRANITE		BASALT

- Numbers indicate the necessary blows to drive 3 six-inch increments, or part thereof, of a split barrel sampler when driven by a 140-pound hammer falling freely for 30 inches: as per ASTM D 1586. The Standard Penetration Resistance (N value) is the sum of the second and third six-inch penetrations. If the sampler is driven less than 18 inches, the N value is represented by the total resistance over the last 12 inches. If the sampler is driven less than 12 inches, logs indicate the number of blows and fraction of increment in inches actually penetrated. Note that a blow count can be listed for a California or Dames & Moore sampler, but that this is not the Standard Penetration Resistance.
- 5) RECOVERY & LOSS: In soil this represents the total length of soil recovered over the amount of sample penetrated.

 In rock this notes the percent core recovery and Rock Quality Designation (RQD).
- 6) SAMPLE DEPTH: A column that provides a reference to the depth below the previously mentioned reference elevation at which samples were taken.
- 7) BOX SAMPLE NO: In the case of rock coring, the box number and core run number are noted. For soils, the designated type and consecutively numbered sample are noted by the following letter;
 - SS Split-Spoon sample, obtained by driving a 2-inch diameter split spoon according to D 1586 to retreve penetration resistance and sample recovery.
 - ST Undisturbed thin-walled tube sample (Shelby Tube)D 1587, obtained by penetration of a 3-inch diameter thin-walled tube using an open or, where indicated, fixed piston sampling head.
 - C Continuous sampler: obtained by drilling a 5-foot long, 2½-inch I.D., CME split barrel sampler into the soil material.
 - DM Liner tube sampler (Dames & Moore), obtained by penetration of a thick-walled, split-barrel sampler containing 2½-inch diameter ring liners.
 - B Bag Sample, obtained by combining disturbed auger cuttings for a large bag sample.

- D Disturbed Sample, obtained from auger cuttings or wash water for a small container sample.
- -J Jar Sample, obtained from any other sample method, but later placed into a jar container due to sample size or disturbance.
- 8) REMARKS: Pertinent observations made and noted by the inspector during drilling. These may include, but are not restricted to, type of drilling, water seepage, fluid loss, time during drilling, material formation, hole termination, pocket penetrometer readings (TSF), piezometer installation, water levels first encountered during drilling and at some time after completion of drilling, and any other pertinent information.
- 9) SOIL STRENGTH: Q_n is the designation of soil strength as measured with a pocket penetrometer. Units are in tons per square foot.

Date Piezometer Installed	N.A.	Time	_	Total Depth of Piezometer	Footage Slotted

Remarks:

Reference point is a rod located in the ponded water north of the site in the ditch southwest of St. Charles Ruck Ruad. The rod is marked in increments of O.I foot and starts with 0:0 at the Luttum and ends at approximately interest at the top. The top of the rod is under water during most of the spring and Parly summer.

APPENDIX D

LABORATORY TEST DATA ON SOIL ENGINEERING PROPERTIES

TABLE D-1
Permeability of Alluvium

Boring	Depth	Sample	Method	Permeability (cm/sec)
D-81	50.0 to 50.6	SS-9a	* Hazen's Formula	2.5×10^{-1}
D-83	73.5 to 97.0	N.A.	** Bailer Test	5.11×10^{-4}
D-83	70.0 to 71.5	SS-12	Hazen's Formula	9.0×10^{-2}
D-83	90.0 to 91.5	SS-14	Hazen's Formula	2.5×10^{-1}
D-85	40.0 to 41.5	SS-8	Hazen's Formula	4.0×10^{-2}
D-85	70.0 to 71.5	SS-11	Hazen's Formula	1.2×10^{-2}
D-87	87.0 to 111.0	N.A.	Bailer Test	3.35×10^{-4}
D-87	100.0 to 101.0	SS-20	Hazen's Formula	6.8×10^{-2}
S-88	30.0 to 31.5	SS~5	Hazen's Formula	2.3×10^{-2}
S-88	29.0 to 40.0	N.A.	Bailer Test	1.45×10^{-3}
D-89	32.5 to 49.0	N.A.	Bailer Test	2.44×10^{-4}

^{*} Hazen's Formula is used to estimate permeability based upon soil grain size distribution. (see Hazen, A., 1930, Water Supply, American Civil Engineers Handbook, John Wiley and Sons, Inc., N.Y.)

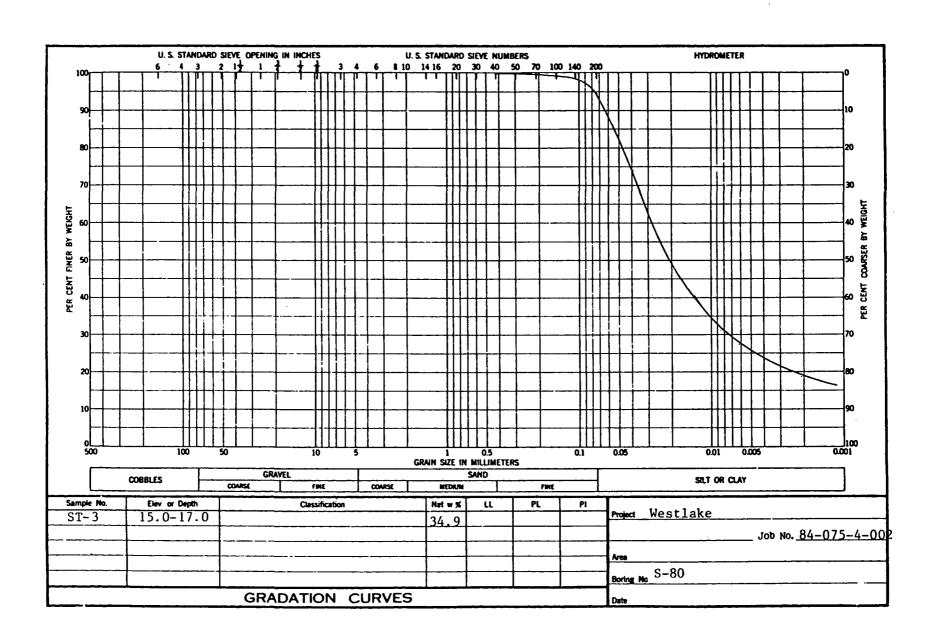

^{**} A bailer test is a field method for determining in-situ permeability.

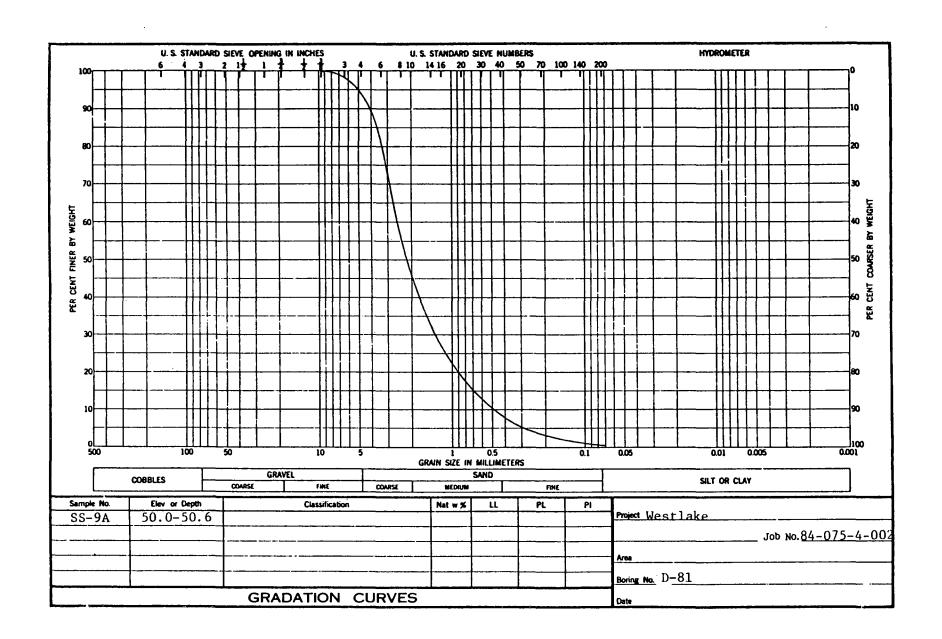

Water was evacuated from the piezometer with a compressed air pump and the rate of recovery recorded. The rate of recovery is related to the soil permeability (see Hvorslev, M. Juul, 1951, Time Lag and Soil Permeability in Groundwater Observations, Waterways Experiment Station, Corps of Engineers, U.S. Army, Vicksburg, Mississippi, Bulletin No. 36.

Subject: GROSS ALPHA AND GROSS BETA RESULTS - WEST LAKE LANDFILL WELLS

Dear Dr. LaRoche:

Enclosed are the results of our gross alpha and gross beta analyses, performed on 32 well water samples, collected May 7 and 8 at the West Lake Landfill site near St. Charles, Missouri. As can be noted, many of the samples exceed the 5 pCi/l gross alpha level requiring isotopic analyses. Therefore, analyses for Ra-226, Ra-228, isotopic uranium, and isotopic thorium have been initiated; results of these analyses will be available in about 3 weeks.

If you have any questions, please contact me at FTS 626-3305.

Sincerely,

bames D. Berger

ABSTRACT

This report presents the results of a radiological survey of the West Lake Landfill, St. Louis County, Missouri, performed by Radiation Management Corporation during the spring and summer of 1981. Measurements were made to determine external radiation levels, concentrations of airborne contaminants and the identity and concentrations of subsurface deposits. Results indicate that large volumes of uranium ore residues, probably originating from the Hazelwood, Missouri, Latty Avenue site, have been buried at West Lake Landfill. Two areas of contamination, the covering more than 15 acres and located at depths of up to feet below the present surface, have been identified. There is no indication that significant quantities of contaminants are moving off-site at this time.

I. INTRODUCTION

In August 1980, Radiation Management Corporation (RMC), under contract to the U.S. Nuclear Regulatory Commission (NRC), performed radiological evaluations of four burial grounds[1]. The first of these sites selected for evaluation was the West Lake Landfill in St. Louis County, Missouri. An initial site visit was completed in August 1980, and a preliminary radiological survey was completed in November 1980. The detailed radiological evaluation was performed in the spring and summer of 1981.

The purpose of this survey was to clearly define the radiological conditions of the West Lake Landfill site. The results of this survey should be sufficient to allow an engineering evaluation to be performed to determine whether remedial actions should and can be taken.

The methods used to evaluate this site include the following:

- 1) measurement of external gamma exposure
 rates 1 meter above the surfaces and
 beta-gamma count rates 1 cm above
 surfaces;
- 2) measurement of radionuclide concentrations in surface soils;
- 3) measurement of radionuclide concentrations in subsurface deposits;
- 4) measurement of gross activity and

radionuclide concentrations in surface and subsurface water samples;

- 5) measurement of radon flux emanating from surfaces;
- 6) measurement of airborne radioactivity; and
- 7) measurement of gross activity in vegetation.

These measurements were performed on-site using two mobile facilities designed by RMC. A small number of samples were returned to the RMC radiological laboratories in Philadelphia for analysis for nuclides which could not be detected in the field, and for quality assurance checks on the field measurements. A set of reference background measurements were made at three locations in the St. Louis area, near West Lake Landfill. In addition, a series of non-radiological measurements were performed to identify the possible presence of toxic or hazardous agents known or believed to have been buried at this landfill.

II. SITE CHARACTERISTICS

The West Lake Landfill is located on St. Charles Rock west of the Taussig Road intersection in Road The site is about one (1) mile Bridgeton, Missouri. northwest of Route 270 and approximately 1-1/2 miles east of the Missouri River. is located in combined It a rural-industrial area, and is bounded on three sides by farm land and on the fourth by St. Charles Rock Road, beyond which are located several commercial and industrial establishments. The nearest residential area is a trailer park located about 3/4 of a mile southeast of the landfill.

The site is approximately 200 acres and consists of a quarry, stone and limestone processing and storage areas, and several active and inactive landfills (Figure 1), which are open to the public during normal working hours. West Lake Landfill keeps track of entries for the purpose of assessing fees for disposal; however, access is not controlled for other reasons. Users are prohibited from disposing of hazardous materials at this site by current Missouri state law.

Studies indicate the landfill is on the alluvial floodplain of the Missouri River. This fact prompted the Missouri Geological Survey, in 1973, to propose classification of the site as hazardous under the then existing operating procedures. In addition, samples from perimeter monitoring wells taken in 1977 and 1978

indicated some movement of leachate into monitoring wells, based on chemcial (not radiological) analyses. However, recent studies by the Department of Natural Resources indicate little or no surface or sub-surface movement of materials from the site[2]. Leachate from the active sanitary landfill is collected and treated on-site. At this time there is no evidence of significant ground water contamination; however, geological reports indicate a potential for such problems.

In May 1976, the St. Louis Post-Dispatch[3] printed a story alleging that radioactive material had been erroneously dumped in the West Lake Landfill in 1973. The source of this material was identified as the Cotter Corporation, Hazelwood, Missouri, Latty Avenue Site.

An NRC investigation conducted by Region III in 1976 [4] concluded that about 7 tons of U308, contained in 8700 tons of leached barium sulfate residues, had been mixed with about 39,000 tons of soil at Latty Avenue and the entire volume disposed of at the West Lake Landfill. The earlier study by the Post-Dispatch (1976) claimed only 9000 tons (presumably the leached barium sulfate residues) had been buried, and that the remaining material had not been disposed of at West Lake. The Post-Dispatch alleged that the contractor hauling the dirt had admitted falsifying invoices for about 40,000 tons of soil. Discussions with site personnel indicated that a large quantity of soil from Latty Avenue had indeed been dumped at West Lake, although

the exact amount was unknown.

A fly-over radiological survey (ARMS flight), performed for the NRC in 1978, showed external radiation levels as high as 100 uR/hr in the area indicated by West Lake personnel as containing the Latty Avenue material. In addition, this survey revealed another possibly contaminated zone in a fill area previously believed to be "clean".

Figure 2 shows the results of the 1978 aerial survey. The area in the southeast fill was believed to contain Latty Avenue material, while that on the northeast boundary was previously unidentified.

In addition to radioactive material, it is known that hazardous chemical wastes have been disposed of at this landfill. Since disposal was unregulated prior to 1973, little is known about the actual materials present. However, it is believed that aside from normal landfill materials, there are chemical industrial wastes in the landfill.

Among the chemical wastes believed to be present are:

waste ink halogenated intermediates

pigments aromatics

oily sludges oils

esters wastewater sludges

alcohols heavy metals

insecticides herbicides

III. RADIOLOGICAL SURVEY METHODS

(A) Measurement of External Radiation Levels

The two areas of contamination were gridded and surveyed for both gamma radiation levels at one meter above the surface, and beta-gamma levels at the ground surface.

The basic pattern at each contaminated area was survey blocks defined by a 10 meter grid system. External gamma levels at one meter were recorded at each grid point at each intersection of two grid lines). Initially, precise exposure rate measurements at a few specially selected grid made with a sensitive Tissue Equivalent points were Ionization Chamber System (described in Appendix I). At the same time, NaI scintillation detector (described in Appendix I) measurements were made and a conversion factor for the NaI count rate versus uR/hr established (See Figure I-3). Once this factor was confirmed, the scintillation detector was used for all grid measurements at relatively low exposure rates. For the few higher rates encountered, a Geiger-Mueller portable survey instrument was used.

At each grid point, an end window G-M tube (described in Appendix I) was used for surface measurements. An open and closed window reading was made at 1 cm, and the ratio of the two used to indicate the presence or absence of surface contamination.

(B) Measurement of Surface Radioactivity

Based on the external surface measurements, surface soil samples were collected for analysis from both contaminated areas. These samples were collected from locations on-site where surface deposits were indicated, as well as locations where the drainage characteristics indicated the possibility that radioactive materials may have been carried or washed away from original burial locations. The soils were dried, ground and sealed in 500 ml aluminum cans for counting on the intrinsic germanium (IG) gamma ray spectroscopy system (described in Appendix I).

Vegetation on-site consisted only of grass and common weeds. Off-site, crops are grown on farm land immediately north and west of the site. Since the possibility of contamination exists here, crop samples were collected where indicated by surface measurements. These samples were dried, crushed and counted as described above.

(C) Measurements of Subsurface Radioactivity

Since it was known that most, or all, of the radioactive materials at the West Lake Landfill have been buried, extensive subsurface monitoring and sampling was required. The purpose of this activity was to determine the depth and lateral extent of subsurface contamination.

A series of holes through and bordering the contaminated deposits were drilled and lined with 4-inch PVC

casing. Each hole was then scanned with a 2" by 2" NaI(Tl) scintillation detector and rate meter system.

Representative holes were then logged using an in <u>situ</u> gamma measurement system consisting of an intrinsic germanium (IG) detector coupled to a multichannel analyzer (described in Appendix I). Field analyses were then made, both qualitatively and quantitatively, thereby eliminating time consuming laboratory analyses and expensive core sampling of each hole. Measurement intervals ranged from 6" to 24", depending upon factors such as hole depth and activity. An occasional core sample was taken to verify the in <u>situ</u> measurements and to confirm the presence or absence of non-gamma emitting nuclides such as Th-230.

(D) Measurement of Radioactivity in Water

Whenever possible, water samples were taken from the bore holes and two off-site monitoring wells. Samples were also taken from standing water, run off water, and leachate liquids. Samples were filtered, evaporated and counted for gross activity, or were filtered and sealed in Marinelli beakers for gamma spectroscopic analysis.

(E) Measurement of Airborne Radioactivity

Measurements were made to determine if the material buried on-site is a source of airborne radioactivity. The isotopes of concern are Ra-226, Ra-224 and/or Ra-223, which decay to Rn-222 Pn-2220 -- 3 Dn 2220 -- 3 D

emanation of radon from the soil, and movement of radon and daughters off-site.

These measurements may be used to determine Rn flux emanation as a source term for off-site dose calculations, or as an indication of the presence of radium at or below the surface. Additional on-site Rn daughter measurements were made to perform working level (WL) determinations.

Radon flux measurements which are to be related to off-site dose calculations were of no value for Rn-219, due to its very short (4 sec) half-life. Therefore, only its long-lived daughters are of concern for off-site exposures. In addition, if the parent (Ra-223) is not within a few millimeters of the surface, Rn-219 is not likely to emanate into the atmosphere [5].

Due to these considerations, only Rn-222 and Rn-220 fluxes were measured. The principal measurement technique was collection of a filtered gas sample from an accumulator and subsequent counting in a radon gas analyzer (described in Appendix 1). Sequential alpha counting, starting immediately after sampling, allowed separation of Rn-222 from Rn-220 (if present). Repetitive samples were taken from several locations during the survey period in an effort to evaluate the effect of fluctuations between individual measurements, due to varying meteorological and soil conditions. A second method using charcoal canisters was also employed as a check on the accumulator technique.

The presence of Rn-219 was determined by detection of its daughters deposited on high volume particulate sample filters, using gamma spectroscopy. Total Rn daughter levels were also estimated by gross alpha activity on particulate filters. From this, a total working level (WL) determination was made.

IV. SURVEY RESULTS

(A) External Radiation Levels

Two areas of elevated external radiation levels have been identified by this survey. Figure 3 shows the two areas as they existed in November, 1980, at the time of the preliminary RMC site survey. As can be seen, both areas contained locations where levels exceeded 100 uR/hr at 1 meter, and in Area 2, gamma levels as high as 3-4 mR/hr were detected. The total areas exceeding 20 uR/hr were about 3 acres in Area 1 and 9 acres in Area 2.

External gamma levels measured in May and July of 1981 shown in Figure 4. These levels had decreased significantly, especially in Area 1, due to continuing activities at the landfill. In both cases, contaminated areas were covered with additional fill material. RMC estimates that about 4 feet of sanitary fill was added to the entire area denoted as Area 1, and that an equal amount of construction fill was added to most of Area 2. As a result, only a small region of a few hundred square meters in Area 1 exceeds 20 uR/hr. In Area 2, the total area exceeding 20 uR/hr decreased by about 10%, and the highest levels are now about 1600 uR/hr, near the Shuman building.

Both areas were marked off in a 10 m by 10 m grid, based on a north-south line erected from a boundary marker, as laid out by a surveying team, as a reference line. Grid

designations are shown in Figures 5 and 6. At each grid point, external gamma levels at 1 m, and beta-gamma count rates at 1 cm, were measured. Results of these measurements are given in Tables 1 and 2.

Beta-gamma measurements at 1 cm from the surface are given in count rates, rather than dose rates, due to the difficulty in measuring beta dose rates accurately with end window G-M tubes. Large differences between open- and closed-window readings indicate the possibility of surface contamination. Little surface contamination was found in Area 1, as would be expected due to fresh land fill cover over nearly the entire area.

Several isolated spots of surface contamination in Area 2 were indicated by beta-gamma measurements, and later confirmed by surface soil sampling. These spots are generally located near the northwest edge of Area 2, which includes the berm that bounds the landfill at that point. Some erosion and run-off is evident along the top of the fill, apparently uncovering deposits of radioactive material in the process. Thus far, fresh construction fill has not been added here, due to the inaccessibility of these spots.

A second region of surface contamination is found just north of the Shuman building. It is not clear why material appears on the surface here, except that it is possible that some digging or excavation has occurred here in the past.

(B) Surface Soil Analyses

A total of 61 surface soil samples were gathered and analyzed on-site for gamma activity. Samples were normally stored 10 to 14 days to allow ingrowth of radium daughters. Concentrations of U-238, Ra-226 (from PB-214 and Bi-214), Ra-223, Pb-211 and Pb-212 were determined for each sample. Locations of surface soil samples are shown in Figures 7 and 8, and the results in Table 3.

In all soil samples nothing other than uranium and/or thorium decay chain nuclides and K-40 was detected. Off-site background samples were on the order of 2 pCi/g for Ra-226. On-site samples ranged from about 1 to 21,000 pCi/g Ra-226, and from less than 10 to 2,100 pCi/g U-238. In those cases where elevated levels of Ra-226 were detected, the concentrations of U-238 were generally anywhere from a factor of 2 to 10 lower. In cases of elevated sample activity, daughter products of both U-238 and U-235 were found.

In general, surface activity was limited to Area 2, as indicated by the surface beta-gamma measurements. Only two small regions in Area 1 showed contamination, both located near the access road across from the site offices.

In addition to on-site gamma analyses, a set of 12 samples were submitted to the RMC radiochemical laboratories for thorium and uranium radiochemical determinations. The

results of these measurements are shown in Table 4. They show that all samples contain high levels of Th-130. The ratio of Th-230 to Ra-226 (Bi-214) is about 20, which indicates an "enrichment" of thorium in these residues, as discussed in Section V.

(C) Subsurface Soil Analysis

Subsurface contamination was assessed by extensive "logging" of holes drilled through the landfill at locations known or thought to contain radioactive materials. Several holes were drilled in areas known to contain contamination, then additional holes were drilled outward in all directions until no further contamination was encountered. A total of 43 holes were drilled, (ll in Area 1 and 32 in Area 2), including 2 off-site water monitoring wells. All holes were drilled with a 6-inch auger and lined with 4-inch PVC casing. The location of these auger holes is shown in Figures 9 and 10.

Each hole was scanned with a 2-inch by 2-incm NaI(T1) detector and rate meter system for an initial indication of the location of subsurface contamination. Based on the initial scans, certain holes were selected for detailed gamma logging using the IG detector and MCA. A total of 19 holes were logged in this manner.

The results of the NaI(T1) counts and IG analyses are shown in Table 5. Concentrations of Bi-214, as determined

by the IG system, ranged from less than 1 to 19,000 pCi/q. For those holes where both NaI(T1) and IG counts were made, a good correlation between gross NaI(T1) counts and Ra-226 concentrations, as determined by in situ analysis of the daughter Bi-214 by the IG system, was found. Figure 11 is a plot of NaI(Tl) count rate versus IG determination of Ra-226, and shows a nearly linear relationship between the at concentrations near the action criteria. The conclusion is that the NaI(Tl) data is a good estimation soil, Ra-226 concentration in so long as the radionuclide mix is reasonably constant. In the case West Lake Landfill, this has been shown to be the case.

It was determined that the subsurface deposits extended beyond areas where surface radiation measurements exceeded action criteria. Figures 12 and 13 show the approximate area of subsurface contamination versus the area of elevated surface radiation levels. The total difference in areas is on the order of 5 acres.

The variations of contamination with depth are shown in Figure 14. As can be seen, the surface elevations vary by about 20 feet, with the highest elevations at locations of fresh fill. Contamination (> 5 pCi/g Ra-226) is found to extend from the surface, in several areas, to a depth of about 20 feet below surface, in two cases. In general, the subsurface contamination appears to be a continuous single layer, ranging from two to fifteen feet thick, located

between elevations of 455 feet and 480 feet and covering 16 acres total area.

In Figures 15-19, representations of the subsurface deposits are provided based on auger hole measurements. These representations are consistent with the operating history of the site, which suggests that the contaminated material was moved onto the site within a few days' time, and spread as cover over fill material. Thus, one would expect a fairly continuous, thin layer of contamination, as indicated by survey results.

(D) Water Analyses

A total of 37 water samples were taken during this survey, 4 in the fall of 1980, and the remainder in the spring and summer of 1981. Results of water analyses are shown in Table 6.

None of the sample alpha activities exceeded the MPC for Ra-226 (the most restrictive nuclide present) in water for unrestricted areas. Only one sample exceeded the EPA gross alpha activity guidelines for drinking water and that was a sample of standing water near the Shuman building. Several samples, including all the leachate treatment plant samples, exceeded the EPA gross beta drinking water standards. Subsequent isotopic analyses indicated that all the beta activity can be attributed to K-40. None of the off-site samples exceeded either EPA standard.

٤.

(E) Airborne Radioactivity Analyses

Both gaseous and particulate airborne radioactivity were sampled and analyzed during this study. Since it was known that the buried material consisted partially or totally of uranium ore residues, the sampling program concentrated on measuring radon and daughters in the air. Two methods were used: the first was a scintillation flask method for radon gas and the second was analysis of filter paper activity for particulate daughters.

A series of grab samples using the accumulator method (described in Appendix I) were taken between May and August of 1981. A total of 111 samples from 32 locations were collected. Results can be found in Table 7. Radon flux levels ranged from 0.2 pCi/sq.m-s in low background areas to 868 pCi/sq.m-s in areas of surface contamination.

At three locations, repetitive measurements were made over a period of two months. These results are plotted in Figure 20. As can be seen, significant fluctuations were observed at two locations. The fact that these fluctuations were real and not measurement artifacts was later confirmed by duplicate charcoal canister samples, as described below.

A total of 35 charcoal canister samples were gathered at 19 locations over a three month period. The results are listed in Table 8, and show levels ranging from 0.3 pCi/sq.m-s to 613 pCi/sq.m-s. On 24 different occasions,

the charcoal canisters and accumulator were placed in essentially the same locations, at the same time, for duplicate sampling. The results of this side-by-side study are presented in Table 9, and show generally good correlation between the two methods.

A set of 10 minute high volume particulate air samples were taken to determine both short-lived radon daughter concentrations and long-lived gross alpha activity. Sample results are shown in Table 10. The highest levels were detected in November, 1980, near and inside the Shuman building. Only these two samples exceed MPC for radon daughters for unrestricted areas.

In addition to the routine 10 minute samples, five 20 minute high volume air samples were taken and counted immediately on the IG gamma spectroscopy system. The purpose of these analyses was to detect the presence of Rn-219 daughters. All samples were taken near surface contamination and are listed in Table 11. In addition to Rn-222 daughter gamma activities, Rn-219 daughters were detected by measuring the low abundance gamma rays of Pb-211. Concentrations of Rn-219 daughters ranged from 6E-11 uCi/cc to 9E-10 uCi/cc.

(F) Vegetation Analysis

Vegetation samples included weed samples from on-site locations and farm crop samples (winter wheat) from the

northwest boundary of the landfill. This location was chosen due to possible run off from the fill into the farm field. No elevated activities were found in these samples.

(G) Non-Radiological Analysis

Six composite samples were submitted to the RMC Environmental Chemistry Laboratory for priority pollutant analysis. Five samples were taken from auger holes (one from Area 1 and four from Area 2) and the sixth from the West Lake leachate treatment plant sludge. The results, shown in Table 12, indicate a significant presence of organic solvents in Area 2 samples. The results of the leachate sludge analysis were not as high as any of the soil samples.

A chemical analysis of radioactive material from both areas was also performed by RMC labs and reported in Table 13. Results show elevated levels of barium and lead in most cases.

(H) Background Measurements and Remedial Action Criteria

Various off-site locations were selected for reference background measurements. The results of these measurements are summarized in Table 14, and can be compared with the established NRC target criteria for remedial action, for this project, shown in Table 15.

v. <u>CONCLUSIONS</u>

Based on survey results, it is evident that the West Lake Landfill contains two areas of surface and/or subsurface contamination. These deposits yield detectable external radiation levels in both areas. However, only an area of less than 0.1 acre in Area 1 exceeds 20 uR/hr, while about 8 acres in Area 2 exceeds the 20 uR/hr criteria. The highest reading detected in the most recent survey was 1.6 mR/hr in Area 2, near the Shuman Building.

Analyses of soil samples from both areas, as well as in situ measurements, show that the contaminants present at West Lake consist of uranium and uranium daughters. Chemical analyses reveal high concentrations of barium and sulfates in the radioactive deposits. These results tend to confirm the reports that this contaminated material is uranium and uranium ore, contained in leached barium sulfate residues, and presumably transferred from the Latty Avenue Site in Hazelwood, Missouri.

Analysis of soils also shows a high Th-230 to Ra-226 ratio. Since the target criteria for Ra-226 is the most restrictive of those contaminants present, it has been assumed that Ra-226 would be the controlling radionuclide for remedial action determinations. However, since Th-230 levels may be from 5 to 50 times higher than Ra-226 concentrations, this assumption may be erroneous. It is

separation of both uranium and radium from the ores, thus "depleting" the ores of uranium and radium, or, "enriching" the residues in thorium. This "enrichment" would also be evident in the U-235 chain, despite the short half-lives of Th-227 and Th-231, since the long-lived Pa-231 would remain in the residues. The concentrations of Pa-231, inferred from Ra-223 determinations, are also shown to be high.

Auger hole measurements show that nearly is located below the contamination present surface, although a few locations near the northwest berm in Area 2 show surface, or near surface, deposits. These deposits range from 2 to 15 feet in thickness, and appear to form a contiguous layer covering an area of about 14 acres (68,000 sq.yd.) in Area 2 and about 2 acres (10,000 sq.yd.)in Area 1. If an average thickness of 2 yards is assumed, the estimated total volume is 150,000 cu.yd., which corresponds to roughly 170,000 tons of soil. This implies that if the source of contamination was the Latty Avenue material, the original volume of 40,000 tons has been diluted by a factor of about 4, which is not unexpected, with the continual movement and spreading of materials during fill operations.

As discussed previously, the auger hole measurements detected deposits exceeding 5 pCi/g Ra-226 within a few feet of the surface, in areas where surface external radiation levels were indistinguishable from normal background levels.

These results confirm suspected difficulties in detecting buried materials with surface measurements, even when using relatively sensitive portable survey instruments.

At no time has radioactivity in off-site water samples been above any applicable guidelines. These results indicate that the buried ore residues are probably not soluble and are not moving off-site via ground water. Onsite samples have shown some gross beta activity above EPA drinking water guidelines (attributable to K-40); however, gross alpha and Ra-226 levels are within limits. The absence of significant contamination in the leachate liquid or sludge is consistent with the implication that the buried material is not moving through the landfill.

As would be expected, radon flux emanation rates were highest at locations of surface, or near surface, contamination. At locations where the material is covered by several feet of fill, flux levels are near background rates.

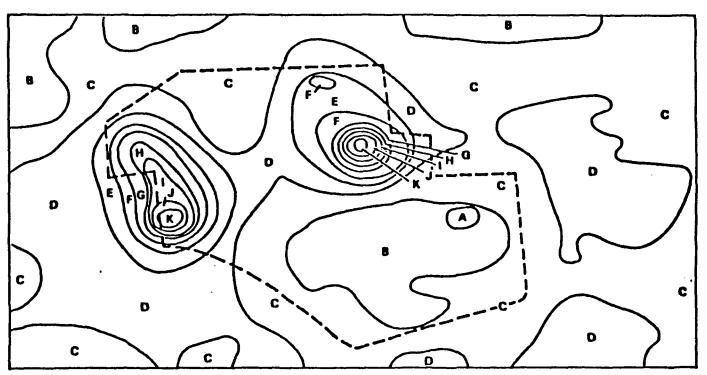

Particulate air samples established indicated the presence of Rn-222 and Rn-219 daughters near the locations of surface deposits. However, concentrations are very low, and do not exceed allowable levels for unrestricted areas, except in one location. In general, cover of a few feet of fill reduces airborne concentrations to near background levels.

The fact that West Lake is an active landfill presents several serious problems for performing radiological assessments and remedial actions. In the first place, as the landfill conditions change, so do the surface radiological characteristics. These changes were evident in the reduction of radiation levels in Area 1 between November 1980, and May 1981. It is possible that future landfill activities will obscure all detectable surface radiation levels at the site.

		Isotopic Ac	tivities
Date/Time	Location	U-238	Ra-226
Composite Sample	All Onsite Samples	9.1E-14+/-1%	4.3E-14+/-1%

Note: Individual sample sensitivities are low due to short sampling time. However, all gross alpha activities except two are less than the maximum permissible concentrations (MPCs) for U-238 or Ra-226, for unrestricted areas, as listed in Appendix B, Table II, of 10CFR20. (These MPCs are 3.0E-12 uCi/cc for either nuclide.) The two exceptions occurred when drilling through contaminated materials.

APPENDIX I

Radiological Survey Instruments and Methods

#### A. Portable Survey Instrument

The portable survey instruments used at West Lake included two complete sets of Johnson equipment, which consist of battery operated rate meters, scalers and alpha, beta and gamma probes. These systems (see Figure I-1) are totally portable and can be used in the field for both measurements and sample counting.

The alpha probes use a ZnS (Ag) scintillation detector; the beta detector is a thin window (1.4mg/cm2 mica) GM tube, and the gamma detector is a 2" by 2" NaI(T1) crystal. The alpha and beta probes were calibrated with "NBS traceable" sources at the RMC calibration facility in Philadelphia and the gamma scintillator was cross-calibrated with a primary ionization chamber system, described below.

#### B. Ionization Chamber System

External gamma dose rates were accurately measured with the RMC constructed Tissue Equivalent Ionization Chamber System (Figure I-2). This system consisted of a 16 liter tissue equivalent, gas filled ionization chamber (Shonka chamber), a Keithley vibrating capacitor electrometer, a printer and battery pack. It is capable of measuring dose rates at background levels to a precision of a few percent.

Since this system is bulky and somewhat fragile, it is not as suited for extensive field measurements as a smaller, lightweight NaI(Tl) portable survey instrument. Therefore,

the NaI(T1) detector was used for the majority of the field gamma measurements. Since this detector's response is energy dependent, it cannot be used as a "micro R meter" unless it is initially calibrated for such use.

The calibration performed by RMC consisted of accurately measuring the exposure rate at several locations at West Lake Landfill, using the Tissue Equivalent Ionization Chamber, then recording NaI(T1) measurements at the same location. In this manner a set of NaI(T1) count-rate versus exposure rates were obtained and a uR/hr calibration factor established, as shown in Figure I-3.

Due to the energy dependence of the NaI detector, this conversion factor will apply only to the radionuclides and geometries for which the calibrations were made. In the case of West Lake, analyses have verified the presence only of naturally occurring nuclides of the uranium series (Ra-226 and daughters), thorium series and potassium. Therefore, the conversion factor established at West Lake will apply only to naturally occurring radionuclides distributed in soil.

#### C. Mobile Lab Gamma Analysis System

The mobile lab gamma analysis system (Figure I-4) consists of a PGT 15% efficient (relative to a  $3^{**} \times 3^{**}$  NaI(Tl) crystal) intrinsic germanium (IG) detector, shield and Tennecomp TP-50 laboratory computer data acquisition

module. The analysis system was calibrated for all counting geometries with an NBS supplied Eu-152 source.

Each count was analyzed by a computer program for determination of gamma energies and peak areas. All results were printed out immediately following analysis on-site, and data was stored on floppy discs for future analysis, as needed.

Samples were sealed in counting containers and stored to allow for complete ingrowth of radon and daughters, whenever possible. In these cases, Ra-226 was determined by counting the daughter Bi-214 gamma-ray lines at 609 and 1764 KeV. Pb-214 was determined by the 295 and 352 KeV lines, U-238 from its 93 KeV line, Ra-223 from its 270 KeV line, Rn-219 from its 401 KeV line, Pb-211 from its 405 and 832 KeV lines, Th-227 from its 237 KeV line and K-40 from its 1462 KeV line.

Typical LLDs for Ra-226 were 0.1 pCi/g in soil and vegetation, and 0.4 pCi/l in water. For Rn-219 daughters on air filters, LLDs were 0.4 pCi/l. The LLD for U-238 in soil was on the order of 1 pCi/g.

## D. Auger Hole Logging System

Detailed logging of selected auger holes was performed with the system shown in Figure I-5. This system consists of a custom designed EG&G Ortec intrinsic germanium detector (10% eff) with a narrow dewar, coupled to a Tracor-Northern

1750 MCA used for data acquisition and initial field evaluations. Data was stored on a tape cassette recorder, then transferred to the lab computer system for final analysis. The entire system, including an NIM module power supply with a bias power supply and amplifier, was powered in the field by a portable 5000 watt gasoline-driven generator.

The logging system was calibrated as described in Attachment 1. Field counting times varied from 2 minutes to 10 minutes at each location, depending upon the level of activity present. Typical LLDs for this system and relatively short count times are 0.3 pCi/g for Bi-214, 1 pCi/g for U-238, 0.2 pCi/g for Pb-212 and 0.1 pCi/g for K-40.

The field use of this system was somewhat limited by initial failure due to high humidity effects on the pre-amp components and thermal insulation of the detector housing. These problems were partially corrected by sealing the detector in an outer container and allowing dry air to flow through the container.

### E. Radon Analysis Systems

Radon flux was determined using the accumulator system shown in Figure I-6, which is similar to those used by Wilkening [1] and others. Accumulation times varied from 15 minutes to 2 hours. Gas samples were drawn and counted in

the EDA Radon Detector, usually 2 hours after sampling, to allow for daughter ingrowth. Standard MSA charcoal canisters were used for the canister method, as described by Countess [2].

All samples were counted for gross alpha or beta activity on the Gamma Products low background gas flow proportional counter, shown in Figure I-7. The system is automatic and can be programmed for a variety of counting parameters.

# INTRINSIC GERMANIUM WELL LOG DETECTOR CALIBRATION

The intrinsic germanium detector was connected to the pulse height analysis system consisting of the following components:

Ortec Model 459 High Voltage Power Supply
Canberra 2011 Spectroscopy Amplifier
Tracor Northern 1750 MCA
Teletype Model 43 Printer

Gain and voltage supply settings were adjusted to obtain an energy spectrum of 0 to 2000 kev, which corresponds to approximately 1 kev per channel.

Calibration of the well logging system was performed using the calibration rig shown in Figure 1. This rig is constructed as a series of four concentric rings surrounding a 6 inch PVC casing. Each ring contains thin plastic tubes 1-1/4" diameter by 36" long. A set of "source rods" and "background rods" were prepared and loaded into these tubes in a variety of configurations for the various calibration and test counts.

The geometry of the rig is such that the distance from the center of the casing (or detector) to the center of the innermost ring is 3.75 inches, to the center of the second ring is 5.0 inches, to the center of the third ring is 6.25

inches, and to the center of the fourth ring is 7.50 inches. All voids between tubes were filled with low background sand. It was determined that the ratio of source volume in each ring to the total ring area was about 0.6. Hence, when source rods were fully loaded into a given ring, the activity counted represented approximately 60% of the total area (volume) the detector viewed, and counts were adjusted accordingly.

Each source tube is a 12 inch high by 1 inch diameter tube filled with a material containing Eu-152. The source material was prepared by mixing the standard Eu-152 source solution with plaster of paris, at a constant ratio designed to give a uniform specific activity of 440 pCi/gram. Background rods were filled with "clean" plaster of paris. Plaster of paris was chosen because of its ease of handling, ability to uniformly distribute the source throughout the material, and its density, which approximates that of common soil. (Density of soil, 1.7-2.3 g/cubic cm; density of plaster, 1.5 g/cubic cm; density of sand, 1.4 g/cubic cm)

Four different configurations of source and blank tubes were used for the calibration. Source tubes were placed three high in one of the four concentric rings of the rig for each count while the balance of the rig was filled with blanks. These configurations correspond to the source material being a radial distance of 3.75, 5.00, 6.25 and 7.50 inches from the detector.

Each configuration was counted for 900 seconds, and the area under each of the eight major Eu-152 photopeaks determined for each count.

Calculation of counts per gamma per gram was determined by the following method:

#### NCNTS/GAMMA/GRAM =

[NCNTS]/[(440pCi/g)(3.7E-2d/s/pCi)(900s)(ABUNDANCEgamma/d)]

For each gamma energy, the net counts/gamma/gram vs distance from the center of the detector was listed. These response curves were then plotted for each energy, for distances and activities which extend to zero net counts. This represents an "infinite" distance from the detector. Using these curves, the total counts from the detector to an infinite distance was calculated by integrating the area under the curve using Simpson's rule for approximating integrals. Of prime importance is the integral from 2 inches to infinity, since this is the area the detector will view when placed inside a 4 inch PVC casing.

Finally, the integrated net count/gamma/gram, from 2 inches to infinity, was plotted vs energy, for each of the Eu-152 photons. With this efficiency curve, a specific activity in soil (pCi/gram) can be determined from a bore hole count, assuming the radionuclide can be identified and its gamma abundance determined. The calculation is:

count, with a 95% confidence level and precision of 0.4 pCi/g.
